Abstract

The composition of the cell nucleus is highly heterogeneous, with different constituents forming complex interactomes. However, the global patterns of these interwoven heterogeneous interactomes remain poorly understood. Here we focus on two different interactomes, chromatin interaction network and gene regulatory network, as a proof-of-principle, to identify heterogeneous interactome modules (HIMs), each of which represents a cluster of gene loci that are in spatial contact more frequently than expected and that are regulated by the same group of transcription factors. HIM integrates transcription factor binding and 3D genome structure to reflect “transcriptional niche” in the nucleus. We develop a new algorithm MOCHI to facilitate the discovery of HIMs based on network motif clustering in heterogeneous interactomes. By applying MOCHI to five different cell types, we found that HIMs have strong spatial preference within the nucleus and exhibit distinct functional properties. Through integrative analysis, this work demonstrates the utility of MOCHI to identify HIMs, which may provide new perspectives on the interplay between transcriptional regulation and 3D genome organization.

Introduction

The cell nucleus is an organelle that contains heterogeneous components such as chromosomes, proteins, RNAs, and subnuclear compartments. These different constituents form complex organizations that are spatially and temporally dynamic (Lanctot et al. 2007; Bonev and Cavalli 2016). Interphase chromosomes are folded and organized in three-dimensional (3D) space by compartmentalizing the cell nucleus (Cremer and Cremer 2001; van Steensel and Belmont 2017), and different chromosomal loci also interact with each other (Bonev and Cavalli 2016). The development of whole-genome mapping approaches such as Hi-C (Lieberman-Aiden et al. 2009) to probing chromatin interactome has enabled comprehensive identification of genome-wide chromatin interactions, revealing important nuclear genome features such as loops (Rao et al. 2014; Tang et al. 2015), topologically associating domains (TADs) (Dixon et al. 2012; Nora et al. 2012), and A/B compartments (Lieberman-Aiden et al. 2009). Nuclear genome organization has intricate connections with gene regulation (Cremer and Cremer 2001; Misteli 2007). In particular, correlations between higher-order genome organization (including chromatin interactions and chromosome compartmentalization) and transcriptional activity have been demonstrated (Guelen et al. 2008; Rao et al. 2014; Chen et al. 2018).

Systems level transcriptional machinery can often be represented by gene regulatory networks (GRNs), which are dynamic in different cellular conditions (Gerstein et al. 2012; Marbach et al. 2016). GRN models the phenomena of selective binding of transcription factors (TFs) to *cis*-regulatory elements in the genome to regulate target genes (Davidson 2006; Lambert et al. 2018). Transcription of co-regulated genes in GRN can be facilitated by long-range chromosomal interactions (Fanucchi et al.

2013) and chromatin interactome exhibits strong correlations with GRN (Kosak et al. 2007; Neems et al. 2016; Zhang et al. 2019). Indeed, network-based representation of both chromatin interactome and GRN has been suggested to analyze different subnuclear components holistically (Rajapakse et al. 2010; Chen et al. 2015). The paradigm of viewing the nucleus as a collection of interacting networks among various constituents can also be extended to account for other types of interactomes in the nucleus. However, whether these interactomes, in particular chromatin interactome and GRN, are organized to form functionally relevant, global patterns remains to be explored. Insights derived from such analysis would also be imperative to better understand the interplay between transcription factors and 3D genome organization, which has been postulated to play important roles in the formation of nuclear genome condensates (Kim and Shendure 2019; Stadhouders et al. 2019), possibly through phase separation with the involvement of super-enhancers and “3D cliques” (Hnisz et al. 2017; Boija et al. 2018; Petrovic et al. 2019).

In this work, as a proof-of-principle, we specifically consider two different types of global interactomes in the nucleus: (1) chromatin interactome – a network of chromosomal interactions between different genomic loci – and (2) a GRN where TFs bind to *cis*-regulatory elements to regulate target genes’ transcription. Many studies in the past have analyzed the structure and dynamics of chromatin interactomes and GRNs as well as cases of coordinated binding of transcription factors on folded chromatin (Rao et al. 2014; Tang et al. 2015; Marbach et al. 2016; Belyaeva et al. 2017; Cortini and Fillion 2018; Ma et al. 2018; Petrovic et al. 2019; Zhang et al. 2019). However, the global network level patterns between chromatin interactome and GRN are still unclear, and algorithms that can simultaneously analyze these heterogeneous networks in the nucleus to discover intricate network structures have not been developed.

Here we aim to identify network structures where nodes of TFs (from GRN) and gene loci (from both chromatin interactome and GRN) cooperatively form distinct types of modules (i.e., clusters). We develop a new algorithm, MOCHI (MOtif Clustering in Heterogeneous Interactomes), that can effectively uncover such network modules, which we call heterogeneous interactome modules (HIMs), based on network motif clustering using a 4-node motif specifically designed to reveal HIMs. HIM integrates transcription factor binding and 3D genome structure to reflect global “transcriptional niches” in the nucleus. Each identified HIM represents a collection of gene loci and TFs for which (1) the gene loci have higher than expected chromatin interaction frequencies, and (2) the gene loci are regulated by the same group of TFs. To demonstrate the utility of MOCHI to identify HIMs based on complex heterogeneous interactomes in the nucleus, we apply MOCHI to five different human cell types, identifying patterns of HIMs and their functional properties through integrative analysis. HIMs have the potential to provide new insights into the nucleome structure and function, in particular, the interwoven interactome patterns from different components of the nucleus.

Results

Overview of the MOCHI algorithm

The overview of our method is illustrated in Figure 1. Our goal is to reveal network clusters in a heterogeneous network such that certain higher-order network structures (e.g., the network motif M in Figure 1A) are frequently contained within the same cluster. The input heterogeneous network in this work considers two types of interactomes: a GRN (directed) between TFs and target genes; and chromatin interaction network (undirected) between gene loci on the genome. For chromatin interactome, for each pair of gene loci within 10Mb, we use the “observed over expected” (O/E) quantity in the Hi-C data (we use $O/E > 1$ as the cutoff in this work, but we found that our main results are largely consistent with different cutoffs; see Supplemental Results) to define the edges in the chromatin interaction network. For GRN, we use the transcriptional regulatory networks from Marbach et al. (2016), which were constructed by combining the enrichment of TF binding motifs in enhancer and promoter regions and the co-expression between TFs and genes. If a TF regulates a gene, we add a directed edge from the TF to the gene. We then merge the chromatin interaction network and the GRN from the same cell type to form a network G with nodes that are either TFs or gene loci together with the directed and undirected edges defined above (Figure 1B).

We specifically consider the network motif M with four nodes, i.e., two gene loci and two TFs in the heterogeneous network with two genes whose genomic loci are spatially more proximal to each other (than expected) in the nucleus and that are also co-regulated by the two TFs (Figure 1A) (see the later section for the justification of this motif). Our goal is to reveal higher-order network clusters based on this particular network motif. In other words, we want to partition the nodes in the network such that this 4-node network motif occurs mostly within the same cluster. Based on the motif, our MOCHI algorithm, which extends the original algorithm in Benson et al. (2016), constructs an undirected, weighted network G_M (Figure 1D) based on the subgraph adjacency matrix W_M , whose elements are the number of times that two nodes are in the same occurrence of motif M in the heterogeneous network G (Figure 1C). We then apply recursive bipartitioning in G_M to find multiple clusters (Figure 1E). We call such clusters HIMs, which, in this work, represent network structures containing the same group of TFs that regulate many target genes whose spatial contact frequencies are higher than expected. Since TFs can regulate multiple sets of genes that may belong to different clusters, different HIMs may overlap by sharing TFs. The algorithm details of MOCHI are in the Methods section.

MOCHI identifies HIMs in multiple cell types

We applied MOCHI to five different human cell types: GM12878, HeLa, HUVEC, K562, and NHEK. The input heterogeneous network of each cell type has 591 TFs, ~12,000 expressed genes, and ~1 million regulatory interactions (Supplemental Table S1). A few examples of HIMs identified in GM12878 are shown in Figure 1F-H, including overlapping HIMs in Figure 1H (see Supplemental File

S1 for the full list of HIMs). We found that the identified HIMs in five cell types cover a majority (62.1-77.2%) of the genes in the heterogeneous networks and share several basic characteristics, including the number of HIMs, the proportion of HIMs sharing TFs with other HIMs, and the number of genes and TFs in HIMs (Supplemental Tables S1, S2). In addition, we found that the identified HIMs in different cell types share similar connections to 3D genome features (Supplemental Results, Supplemental Table S2).

Note that the 4-node motif M was chosen specifically for uncovering HIMs derived from TFs and genes based on 3D genome organization. Specifically, we compared the 4-node motif M against its subgraphs bifan and triangle motifs (Supplemental Figure S1A). The bifan and triangle motifs do not explicitly and simultaneously encode the spatial proximity between genes and the co-regulation between TFs. We found that the clusters based on the 4-node motif M have better clustering features, including triangle density and motif M density (see Supplemental Results, Supplemental Figures S1, S2, Supplemental Table S3). These advantages highlight the necessity of using the 4-node motif M to identify HIMs.

To further assess that the genes in a HIM are indeed co-regulated by the same TF, we used the available ChIP-seq data of 26 TFs in GM12878 and K562 cells from the ENCODE portal (<https://www.encodeproject.org>) (Davis et al. 2018). We found that for all the HIMs in GM12878 or K562 with these 26 TFs, more than half (55.85%) of them have $\geq 50\%$ of their genes with corresponding TF ChIP-seq peaks within 10kb of the transcription start site, further suggesting that the genes in HIMs identified by MOCHI share regulatory TFs. Note that TF ChIP-seq data were not used to infer the input GRNs. In addition, MOCHI can robustly identify HIMs with different parameters in various cell types (Supplemental Results and Supplemental Figure S3). These results demonstrate that MOCHI can reliably discover HIMs across multiple cell types.

HIMs exhibit advantages over conventional GRN clusters in multiple aspects

Conceptually, one key difference between HIMs and clusters in conventional GRN (using GRN data only) is that HIMs have spatial constraints such that genes in HIMs are in spatial contact more frequently than expected. To investigate potential advantages of HIMs with a fair comparison between HIMs and GRN clusters, we modified the MOCHI framework to identify GRN clusters from GRN data used in this study (see Supplemental Results). We first sought to assess the connections with fundamental genome functions, including replication timing and gene expression. Compared to genes in GRN clusters, we found that genes in HIMs replicate earlier and replicate with more similar timing (Supplemental Figures S4A-B, S5). Genes in HIMs also express at higher levels and at more similar levels (Supplemental Figure S5). These results suggest the stronger connection between HIMs and fundamental genome functions as compared to GRN clusters.

We next compared HIMs with GRN clusters in terms of the enrichment of genes affected by eQTLs

using the GEUVADIS dataset (The 1000 Genomes Project Consortium 2015). Here we call a cluster enriched with an eQTL if (1) the cluster has more than 5 genes, (2) the cluster and eQTL share at least 2 genes, and (3) the number of shared genes is significantly higher than those of randomly selected equal-sized expressed gene sets on the same chromosome ($p < 0.05$, hypergeometric test). We found that nearly half (49.44%) of GM12878 HIMs are enriched in genes affected by eQTLs, which is significantly higher than the enrichment (36.5%) based on GRN clusters ($p = 0.001$, Supplemental Figure S4C), suggesting that genes in HIMs are more likely to share eQTLs. Similar enrichment analysis for genes affected by SNPs in GWAS (based on the NHGRI-EBI GWAS Catalog) revealed that HIMs have a significantly higher proportions of gene clusters that are affected by GWAS SNPs than GRN clusters ($p \leq 7.38 \times 10^{-4}$, Supplemental Figure S6). In addition, we extracted a subset of GWAS SNPs that are associated with blood-related disorders and assessed their enrichment in HIMs in blood-related cell lines GM12878 and K562. We found that HIMs have higher proportion of genes affected by such SNPs than GRN clusters ($p \leq 0.035$, Supplemental Figures S4E, S6). In particular, there are 4 blood-related disorders where genes affected by their associated SNPs are enriched in HIMs but not in GRN clusters (Supplemental Table S4). On the other hand, there is no blood-related disorder where genes affected by their SNPs are enriched in GRN clusters but not in HIMs. These results further demonstrate the greater functional relevance of HIMs as compared to GRN clusters.

We then assessed the level of involvement of long-range enhancer-gene interactions in HIMs and in conventional GRN clusters (also see Supplemental Results). We specifically focused on the clusters in which the majority ($\geq 50\%$) of genes are connected to enhancers that are located within the wide genomic region covered by the HIM through long-range enhancer-gene interactions (example HIMs in Supplemental Figure S4F-H). The proportion of such HIMs is significantly higher than that of conventional GRN clusters across cell types (Supplemental Figure S7, Supplemental Results). These results indicate that HIMs have stronger connection with long-range enhancers, which also reflects the advantage of HIMs that integrate TF binding and 3D genome organization.

Taken together, the comparison with conventional GRN clusters highlight the importance of having 3D genome spatial constraints to identity HIMs. In addition, these analyses also demonstrate that HIMs have overall stronger significance in biological functions as compared to GRN clusters. For the rest of the paper, we characterize structural and functional properties of HIMs and investigate the dynamics of HIMs across different cell types.

HIMs show strong preference in spatial localization relative to subnuclear structures

Next, we analyzed the spatial localization of HIM in the nucleus. Recently published SON TSA-seq and Lamin B TSA-seq datasets quantify cytological distance of chromosome regions to nuclear speckles and nuclear lamina, respectively (Chen et al. 2018). In K562, which is currently the only cell type with published TSA-seq data, 60.7% of the HIMs have mean SON TSA-seq score higher than 0.284 (80-th percentile of the SON TSA-seq score), suggesting that the genes in these HIMs, on

average, are within $0.518\mu\text{m}$ (estimated in Chen et al. (2018)) of nuclear speckles (Figure 2A). Compared to the genes in the K562 heterogeneous network but not assigned to HIMs, the genes in HIMs have higher SON TSA-seq score and lower Lamin B TSA-seq score ($p < 2.22 \times 10^{-16}$; Supplemental Figure S8).

We specifically looked at those HIMs that are away from the nuclear interior. Figure 2B shows one HIM (#541) that is close to nuclear lamina (mean Lamin B TSA-seq score 0.593, mean SON TSA-seq score -0.642). This HIM has 9 TFs co-regulating 6 genes that span 6.78 Mb on Chromosome 3. The Hi-C edge density (see Supplemental Methods) among these genes is 0.667, suggesting that these 6 genes as a group are spatially closer to each other than expected through chromatin interactions. The SON TSA-seq scores of the 6 genes are low but tend to be the local maxima (i.e., small peaks within valleys), while the Lamin B TSA-seq scores are high but tend to be the local minima (i.e., small valleys within peaks), suggesting that these gene loci are localized more towards the nuclear interior than their surrounding chromatin. Five out of the 6 genes are expressed with $\text{FPKM} \geq 3.4$. The gene *RPL15* in this HIM is a K562 essential gene (Wang et al. 2015). The TFs CDX1, HOXA9, and HOXA10 are involved in leukemia and hematopoietic lineage commitment according to GeneCards (Safran et al. 2010). This suggests that even though HIM #541 is a HIM away from nuclear speckle, it may play relevant functional roles in K562.

Recently, Quinodoz et al. (2018) reported that inter-chromosomal interactions are clustered around two distinct nuclear bodies, nuclear speckles and nucleoli, as hubs. By comparing with the genomic regions organized around nucleolus based on data from the SPRITE method in GM12878 (Quinodoz et al. 2018), we found that a vast majority (85.4%) of the GM12878 HIMs do not have genes close to the nucleolus. Earlier work estimated that only 4% of the human genome is within nucleolus-associated domains (Nemeth et al. 2010). It is therefore expected that only a small number of HIMs would be close to the nucleolus. Indeed, we found that there are only 30 (4.62%) GM12878 HIMs with all their genes near the nucleoli. 16 out of these 30 HIMs have at least one TF protein located close to nucleoli according to protein subcellular locations from the human protein atlas (Thul et al. 2017). For example, HIM #267 has 4 TF regulators: ETS1, ETV6, PPARG, and PTEN, where ETV6 is known to localize to the nucleoli.

Earlier work from Hi-C data showed that at megabase resolution the interphase chromosomes are segregated into A and B compartments that are largely active and inactive in transcription, respectively (Lieberman-Aiden et al. 2009). Chromosome regions in B and A compartments have nearly identical agreements, respectively, with lamina associated domains (LADs) and inter-LADs (i.e., more towards interior) (van Steensel and Belmont 2017). Compartment A regions also replicate earlier than compartment B regions (Pope et al. 2014). We found that the genes in HIMs are preferentially in A compartments and replicated earlier across cell types. Specifically, 57.4% of HIMs have genes that are all in A compartments in K562 (Figure 2C). We also found that the genes in HIMs as a whole are more enriched in A compartments ($p < 2.22 \times 10^{-16}$, hypergeometric test; Figure 2D). Compartment A can

be further subdivided into A1 and A2 subcompartments in GM12878 (Rao et al. 2014) at a finer scale. Among the 369 GM12878 HIMs with genes all in A compartments, 198 (53.66%) HIMs have $\geq 80\%$ of their genes in A1 subcompartments, 60 (16.26%) HIMs are in A2 subcompartments, and the remaining 111 HIMs span both A1 and A2 compartments. Additionally, we found that the genes assigned to HIMs have much earlier replication timing than the other genes ($p < 2.22 \times 10^{-16}$; Figure 2E). We also observed that the genes (on the same chromosome) that are in HIMs tend to have more similar replication timing as compared to the genes (on the same chromosome) that are not in HIMs (Supplemental Figure S9). These patterns can also be observed in other cell types (Supplemental Figure S9).

Taken together, these results have revealed that HIMs have strong preference to localize towards the nuclear interior in active compartments with the majority of them being in proximity of the nuclear speckles and replicating earlier.

HIMs are enriched with essential genes, super-enhancers, and PPIs

Next, we explored the functional properties of HIMs. We grouped the genes assigned to HIMs into one set and the genes in the heterogeneous network that are not assigned to HIMs into another set. For a fair comparison, we group the gene sets by chromosome number. We call these clusters merged-HIM clusters and non-HIM clusters accordingly. We first looked at gene essentiality (Wang et al. 2015) (Supplemental Methods). We found that genes assigned to HIMs are enriched with essential genes across all five cell types. For example, 12.7% of the genes assigned to HIMs in K562 are K562 essential genes, which is significantly higher than the proportion (7.79%) of the genes not assigned to HIMs ($p = 1.13 \times 10^{-12}$; Figure 3A). This observation is also present on different chromosomes (Supplemental Figure S10A). Across the cell types, genes assigned to HIMs consistently have higher proportions of essential genes than those not assigned to HIMs ($p \leq 2.17 \times 10^{-6}$; Supplemental Figure S10B). Regarding gene expression level, we found that genes assigned to HIMs are more highly expressed and expressed at more similar levels (Figure 3B, Supplemental Figure S11).

Super-enhancers are known to be associated with many cell type-specific functions (Hnisz et al. 2013). To study the connections between HIMs and super-enhancers, we computed the cluster-size normalized number of super-enhancers annotated in Hnisz et al. (2013) that (1) have Hi-C contacts with and (2) are close to (window size=50kb) at least one gene in each cluster. We found that HIMs are enriched with spatial contacts with super-enhancers. Specifically, the merged-HIMs have at least 6-fold higher normalized number of super-enhancers than the non-HIMs across cell types (Figure 3C, Supplemental Figure S12). This significant pattern is consistent with varied window sizes from 20kb to 1Mb (Supplemental Figure S12).

Protein-protein interactions (PPIs) can further stabilize TF-DNA binding of the interacting TFs (Lambert et al. 2018). We asked whether TFs in the same HIM tend to have more PPIs with each other.

We computed the density of the sub-PPI network induced by the TFs in a HIM, where the PPI network is based on 591 TF proteins used in this study (Supplemental Methods). We found that TFs within HIMs are enriched with PPIs among themselves as compared to random cases selected from the 591 TFs. For example, in GM12878, TFs NR3C1 and TFEB, which are master regulators (Hnisz et al. 2013), co-regulate 8 genes with the other 7 TFs in a HIM (Figure 3D). The density of this particular sub-PPI network is 0.389 which is 2.46 times higher than the average density (0.158) of the random cases. Overall, the median density of the sub-PPI networks induced by TFs in the identified HIMs in GM12878 is 0.214, much higher than the random cases ($p < 2.22 \times 10^{-16}$; Figure 3E). This observation also holds in other cell types in this study (Supplemental Figure S13). We also found that the significance is not affected by the different number of TFs across HIMs (Supplemental Figure S13).

These results suggest that the genes and TFs involved in HIMs likely perform critical roles, which are manifested by the level of gene essentiality of target genes, engagement of super-enhancers, and enrichment of PPI among TFs.

Genes in HIMs exhibit stability and variability across cell types

To study how HIMs change among different cell types, we first focused on the assignment of genes to HIMs in different cell types. Through pairwise comparison, we found that the genes assigned to HIMs have the highest degree of overlap between GM12878 and K562 as compared to the other cell types, which is consistent with the fact that both GM12878 and K562 are from human hematopoietic cells (Supplemental Figure S14A). Comparisons among all five cell types showed that 3,025 genes are consistently assigned to HIMs, accounting for 30.91% to 40.06% of genes that are in the HIMs in each cell type (Figure 4A). In contrast, only a small fraction ($\leq 5.93\%$) of genes are uniquely assigned to HIMs in each cell type.

The genes consistently and uniquely assigned to HIMs are enriched with distinct functional terms using DAVID (Huang da et al. 2009) (Supplemental Table S5). The genes consistently assigned to HIMs are strongly enriched with functions related to essential cellular machinery, whereas the genes uniquely assigned to HIMs in a particular cell type are enriched with more cell type-specific functions. An example is NHEK HIM #107 (Figure 4B). Among the 6 genes in this HIM, *DSCI*, *DSC3*, *DSG1* are not assigned to HIMs in the other cell types. These 6 genes are involved in the keratinization pathway based on GeneCards (Safran et al. 2010). We further assessed the assignment of housekeeping genes (Eisenberg and Levanon 2013) and essential genes to HIMs. We found that for both sets of genes, the majority ($\geq 84\%$) of them are assigned to HIMs consistently in at least 3 out of the 5 cell types (Figure 4C), suggesting that the genes with crucial functions tend to form spatial clusters across multiple cell types.

We next analyzed the variability of HIMs in terms of spatial proximity to subnuclear compartments. We found that 15 out of the 30 HIMs close to nucleoli in GM12878 (based on the data from Quinodoz

et al. (2018)) have mean SON TSA-seq score ≥ 0.284 in K562 (based on the data from Chen et al. (2018)) (Figure 4D). In other words, these HIMs are involved in a change of spatial position from nucleoli to speckle between GM12878 and K562. One example is HIM #267 in GM12878 which has the highest mean SON TSA-seq score (2.41) in K562. The 10 genes (in HIM #267 in GM12878) together with another 8 genes form a new HIM (#628) in K562. This GM12878 HIM #267 has four TFs: ETS1, ETV6, PPARG, and PTEN. On the other hand, the K562 HIM #628 has four different TFs: KLF4, NFKB1, STAT3, and WT1.

To compare the detailed membership changes of HIMs across cell types, we computed Jaccard indices, denoted by J_{TF} and J_{gene} , of the TF members and gene members between HIMs from two different cell types, respectively. We found that the gene members undergo a moderate change from one cell type to another, whereas the TF members change at a much higher rate. J_{gene} has a median of 0.096 and it is higher than the expected J_{gene} between random gene sets while controlling the set size and chromosome number (median ratio=14.12, Figure 4E). On the other hand, J_{TF} has a median of 0.017, which is close to the expected J_{TF} between randomly selected control TF sets (median ratio=0.878, Figure 4E). There are at least two factors jointly contributing to these observations. First, the Hi-C interaction networks and GRNs are highly cell type-specific, as 66% chromatin interactions and 31.4% GRN interactions only exist in one cell type (Supplemental Table S6). Second, given a HIM identified in a cell type, the motif M density of the HIM (see Supplemental Methods) has higher fold change than the Hi-C edge density of the HIM in another cell type ($p < 2.22 \times 10^{-16}$; Figure 4F). In other words, the co-regulation relationships of the TFs on the genes within HIMs change more often across cell types than the spatial proximity relationships between the gene loci. However, we observed that if HIMs from two different cell types share a higher number of housekeeping genes, they tend to have a higher J_{TF} (Figure 4G). We found a similar pattern for essential genes (Supplemental Figure S14B).

Conserved and cell type-specific HIMs have distinct properties

Motivated by the gene membership dynamics of HIMs across cell types, we further classified HIMs into conserved and cell type-specific HIMs. For HIMs in a given cell type, we call a HIM conserved if it shares a significantly high proportion of genes ($J_{gene} \geq 1/3$, $p \leq 0.001$, Bonferroni adjusted hypergeometric test) with at least one HIM in other cell types (i.e., the HIM is recurrent). Note that $J_{gene} \geq 1/3$ represents that two equal-sized gene sets share more than half of their genes. The rest are called cell type-specific HIMs. Figure 5 shows a cell type-specific HIM, HIM #712, in K562 and its changes in other cell types. This HIM covers 9 genes on Chromosome 11. These genes spatially contact each other at higher frequencies than expected (Figure 5A) and are co-regulated by TFs BCL6B and CPEB1 in K562 (Figure 5B). In other cell types, at most 4 out of the 9 genes are assigned to HIMs (Figure 5C). We found that this HIM has K562-specific chromosomal structures and functional annotations. The genomic region covering the genes in the HIM is in A compartment in K562 but switches to B compartment in other cell types (Figure 5D). One nearby upstream region is annotated as a super-enhancer only in K562 (Hnisz et al. 2013) (Figure 5E). Many genomic loci are

annotated as transcriptionally active states, such as enhancers, promoters, or transcribed states in K562, but not in other cell types based on ChromHMM (Ernst and Kellis 2012) (Figure 5F). The genes *MRPL16*, *OSBP*, and *PATL1* are essential genes in K562. We compared the 3D structural representations of the chromosome region centered on genes in HIM #712. We ran Chrom3D (Paulsen et al. 2018) 100 times to construct 100 possible 3D structures in each cell type to enable statistical comparisons. One possible 3D structure in K562 is shown in Figure 5A. We found that the chromosome region covering the genes in the HIM has specific 3D structure in K562. The upstream super-enhancer is spatially closest to the genes in HIM #712 in K562 (Supplemental Figure S15A). The chromosome region covering the super-enhancer and the genes in HIM #712 are spatially more proximal to each other as compared to the flanking regions (\pm 500kb) in 3D space in K562 (Supplemental Movie S1, Supplemental Figure S15B). This example illustrates that the K562-specific HIM has specific chromatin organization and potential biological functions. Together, our comparisons reveal that in general conserved HIMs have stronger cluster features, tend to be closer to nuclear interior, and have higher expression levels. On the other hand, cell type-specific HIMs have a higher proportion of cell type-specific genes (Supplemental Results, Supplemental Figures S16, S17).

Discussion

To better understand the heterogeneous nature of different components in the nucleus, new computational models are needed to jointly consider different types of molecular interacting networks. In this work, we developed MOCHI to specifically consider two types of different interactomes in the nucleus: (1) a network of chromosomal interactions between different gene loci, and (2) a GRN where TFs bind to the genomic loci with *cis*-regulatory elements to regulate target genes. MOCHI is able to identify network patterns where nodes of TFs (from GRN) and gene loci (from both chromatin interactome and GRN) cooperatively form distinct network clusters, which we call HIMs, by utilizing a new motif clustering framework for heterogeneous networks. To the best of our knowledge, this is the first algorithm that can simultaneously analyze these heterogeneous networks within the nucleus to discover important network structures and properties. By applying MOCHI to five different human cell types, we made new observations to demonstrate the biological relevance of HIMs in 3D nucleome.

Our method has multiple methodological contributions. We further extended the motif conductance clustering method (Benson et al. 2016) to find overlapping HIMs in heterogeneous networks. Our work shows the utility of our new algorithm to identify HIMs based on complex heterogeneous molecular interactomes. In addition, our method can be further modified to identify other types of potential HIMs in heterogeneous networks by replacing the 4-node motif *M* with relevant motifs, especially when additional types of interactomes are included. For example, in addition to considering chromatin interactions and protein-DNA interactions as we did in this work, it would be of interest to incorporate other types of relevant interactomes in the nucleus, such as the RNA-chromatin interactome (Nguyen et al. 2018).

How can we explain the formation of HIMs? In Figure 6, we illustrate a possible model of HIMs within the nucleus. HIMs (light pink domains) are toward the interior with a group of interacting TFs and chromatin loci as “transcriptional niche”. The set of TFs in a HIM cooperatively regulate target genes, which also have higher contact frequency than expected. Note that this is conceptually consistent with recently reported co-localized TF pairs (Ma et al. 2018), condensates (Chong et al. 2018; Sabari et al. 2018; Kim and Shendure 2019), and 3D clique (Petrovic et al. 2019). Some of these TF clusters may be related to the localization preferences of TFs in nuclear compartments, such as nuclear speckles that are enriched with various transcriptional activities (Spector and Lamond 2011; Chen et al. 2018). Indeed, we found that the majority of the identified HIMs are close to nuclear speckles. The definitions of HIMs may also have intrinsic connections with the emerging findings on the mechanism of nuclear subcompartment formation, where TFs and their potential target genes/chromatin are trapped by localized liquid-like chambers through phase separation (Hnisz et al. 2017; Shin and Brangwynne 2017; Chong et al. 2018). It has been suggested that phase separation may help explain the formation of super-enhancer mediated gene regulation (Hnisz et al. 2017; Boija et al. 2018), although the exact roles of TFs in this process remain elusive (Kim and Shendure 2019; Stadhouders et al. 2019). From our analysis, we found that genes assigned to HIMs are enriched with contacts with super-enhancers. The genes consistently assigned to HIMs are enriched with essential biological processes related to chromosomal organization and transcription. However, the detailed formation mechanisms for HIMs, which may involve both *cis* elements and *trans* factors, remain to be investigated. It would also be important to delineate the different roles of both different TFs and different genes in forming the HIMs, as some of them may be necessary and others may be redundant for the stability of HIMs. In addition, more experimental data are needed to further evaluate the functional significance of HIMs. For example, although we observed connections between HIMs and 3D genome organization features, the intricate functional relevance among these different higher-order nucleome units that jointly contribute to gene regulation in different cellular conditions has yet to be revealed. Nevertheless, HIMs may become a useful type of nuclear genome unit and informative resource in integrating heterogeneous nucleome mapping data, which has the potential to provide new insights into the interplay among different constituents in the nucleus and their roles in 3D nucleome structure and function.

Methods

Brief introduction to homogeneous network clustering by motif conductance

We first review higher-order network clustering method that can identify a cluster of nodes S based on motif conductance (defined below). We then introduce our algorithm MOCHI in the next subsection. Let G be an undirected graph with N nodes and A be the adjacency matrix of G . $[A]_{ij} \in \{0,1\}$ represents the connection between nodes i and j . The *conductance* of a cut (S, \bar{S}) , where S is a subset of the nodes and \bar{S} the complementary set of S is defined as:

$$\varphi_G(S) = \frac{\text{cut}_G(S, \bar{S})}{\min[\text{Vol}_G(S), \text{Vol}_G(\bar{S})]}, \#(1)$$

where $\text{cut}_G(S, \bar{S}) = \sum_{i \in S, j \in \bar{S}} [A]_{ij}$ is the number of edges connecting nodes in S and \bar{S} . $\text{Vol}_G(S) = \sum_{i \in S} \sum_{j=1}^N [A]_{ij}$ is the sum of the node degree in S . Moreover, the conductance of the graph G , φ^G , is defined as $\min_S \varphi_G(S)$. The S that minimizes the function is the optimal solution. Finding the optimal S is NP-hard, but spectral methods such as Fiedler partitions can obtain clusters effectively (Chung 2007). Recently, the conductance metric has been generalized to motif conductance (Benson et al. 2016; Tsourakakis et al. 2017), where a motif refers to an induced subgraph. The motif conductance computes $\text{cut}_G(S, \bar{S})$ and $\text{Vol}_G(S)$ based on a chosen n -node motif. When $n = 2$, the motif is an interaction that reduces the motif conductance to conductance in Eq. (1). When $n \geq 3$, the motif conductance may reveal new higher-order organization patterns of the network (Benson et al. 2016). A more recent network clustering method that incorporates network higher-order structures has been developed in the setting of hypergraph clustering (Li and Milenkovic 2017), which includes the motif conductance as a special case. However, one key limitation of the aforementioned methods is that they cannot identify overlapping clusters, which is a crucial feature of the heterogeneous networks that we want to achieve in this work.

MOCHI – Higher-order network clustering to identify HIMs in a heterogeneous network

We developed a higher-order network clustering method based on network motif to identify overlapping HIMs in a heterogeneous network by extending the approach in Benson et al. (2016). We call our method MOCHI (MOTif Clustering in Heterogeneous Interactomes). We illustrate the workflow of MOCHI in Figure 1. First, we select a specific heterogeneous 4-node network motif M (Figure 1A). In M , two nodes are TFs and the other two nodes are genes. Both TFs regulate the two genes and the two genes are spatially more proximal to each other than expected. The motivation for choosing the subgraph M is that it is the building block of HIMs given that our goal is to discover a group of genes that have contact with each other more frequently than expected and also share TF regulators. As compared to simpler motifs (e.g., 3-node motif where one node is TF), our 4-node motif defined here has the advantage of simultaneously considering a pair of genomic loci that interact with each other and that are co-regulated by the same pair of TFs.

Conceptually, our method searches for HIMs with two goals. The TFs and genes in the same HIM should be involved in many occurrences of M . Additionally, HIM should avoid cutting occurrences of M , where a cut of occurrences of M means that only a subset of TFs and genes in the occurrences of M are in the HIM node set. More formally, our method aims to find HIMs with the node set S that minimizes the motif conductance:

$$\varphi_M(S) = \frac{\text{cut}_M(S, \bar{S})}{\min[\text{Vol}_M(S), \text{Vol}_M(\bar{S})]} \cdot \#(2)$$

We first introduce some notations before we explain $\varphi_M(S)$ and provide definitions of $\text{cut}_M(S, \bar{S})$ in Eq. (3) and $\text{Vol}_M(S)$ in Eq. (4). Let G be the given heterogeneous network (e.g., Figure 1B). Let \mathbb{M} be the set of occurrences of the motif M in G . For simplicity and without confusion, we also denote an occurrence of the motif M as M . Let V_M be the node set of the 2 TFs and 2 genes in $M \in \mathbb{M}$. In Eq. (2), $\text{cut}_M(S, \bar{S})$ is the number of occurrences of the subgraph M that are cut by S . Formally,

$$\text{cut}_M(S, \bar{S}) = \sum_{M \in \mathbb{M}} \mathbb{1}(|V_M \cap S| \in \{1, 3\}) + \alpha \sum_{M \in \mathbb{M}} \mathbb{1}(|V_M \cap S| = 2), \quad \alpha > 1, \#(3)$$

where $\mathbb{1}$ is an indicator function. Here, $\text{cut}_M(S, \bar{S})$ distinguishes the number of nodes of the 4-node motif M being assigned to S and \bar{S} . Specifically, it adds a higher penalty for the cut to the cases where two nodes in M are assigned to S and two nodes are assigned to \bar{S} (i.e., $\mathbb{1}(|V_M \cap S| = 2)$ in Eq. (3)), as compared to the cases where one node or three nodes are assigned to S (i.e., $\mathbb{1}(|V_M \cap S| \in \{1, 3\})$ in Eq. (3)), by letting $\alpha > 1$ in Eq. (3). This is because the 1-vs-3 split could still keep interaction information from both GRN and chromatin interaction network, and the 2-vs-2 split will lose either of the information. We show that when $\alpha = 4/3$ in Eq. (3) the clustering results would be near optimal (Supplemental Methods). Thus, α is set to $4/3$ in this work. $\text{Vol}_M(S)$ is the sum of the number of occurrences of M containing nodes in S , which is defined as:

$$\text{Vol}_M(S) = \sum_{i \in S} \sum_{M \in \mathbb{M}} \mathbb{1}(i \in V_M). \#(4)$$

Similarly, we define the subgraph conductance of the graph G based on the motif M , φ_M^G as $\min_S \varphi_M(S)$. Note that the notation G is excluded from the notations cut_M , Vol_M , φ_M^G , and $\varphi_M(S)$ that are dependent on both heterogeneous network G and motif M . This is because including G would likely confuse this set of notations with a set of notations related to homogeneous network G_M derived from heterogeneous network G and network motif M later in this section. In the following procedures of the algorithm, we show that the motif conductance is equivalent to the normal conductance in a projection of the graph by calculating the subgraph adjacency matrix. Thus, finding the set S that achieves the minimum subgraph conductance is also NP-hard, following that it is NP-hard to find the minimal $\varphi_G(S)$. We describe our algorithm MOCHI to find HIMs that approximate the solution.

1 – Calculate subgraph adjacency matrix $W_M(G)$

We first calculate the subgraph adjacency matrix $W_M(G)$ by:

$$[W_M(G)]_{ij} = \sum_{M \in \mathbb{M}} \mathbb{1}(i \in V_M, j \in V_M), \#(5)$$

where $[W_M(G)]_{ij}$ is the number of occurrences of the subgraph M in G that cover both i and j (see example in Figure 1C). For example, if both i and j are TFs, $[W_M]_{ij}$ reflects the number of paired gene loci that are spatially more proximal to each other and that are also co-regulated by TFs i and j . If both i and j are genes, $[W_M]_{ij} = 0$ if i and j are not spatially more proximal to each other. Otherwise, $[W_M]_{ij}$ is the number of paired TFs that co-regulate i and j . Generally, $W_M(G)$ is symmetric and $[W_M(G)]_{ij} \geq 0$. Thus $W_M(G)$ can be viewed as the adjacency matrix of an undirected weighted network. Let G_M denote the network with $W_M(G)$ as the adjacency matrix (see Figure 1D for example). It is important to note that there are genes or TFs that may not be in any occurrence of M , which would lead to zero vectors in the corresponding rows and columns in $W_M(G)$. These singleton nodes in G_M would be removed before the next step.

2 – Apply Fiedler partitions to find a cluster in G_M

We utilize Fiedler partitions similar to the algorithm in Benson et al. (2016) to find a cluster S in graph G_M , where $\varphi_{G_M}(S)$ is close to the global optimal conductance of the graph: $\varphi(G_M)$. Recall that $\varphi(G_M)$ is the minimum of $\varphi_{G_M}(S_1)$ over all possible sets S_1 . The method is described as follows.

- Calculate the normalized Laplacian matrix of $W_M(G)$:

$$\mathcal{L} = \mathbf{I} - D_{G_M}^{-1/2} W_M(G) D_{G_M}^{-1/2}, \#(6)$$

where \mathbf{I} is a identity matrix, D_{G_M} with $[D_{G_M}]_{ii} = \sum_{j=1}^N (W_M(G))_{ij}$ is the diagonal degree matrix of G_M .

- Calculate the eigenvector v of the second smallest eigenvalue of \mathcal{L} .
- Find the index vector $(\alpha_1, \dots, \alpha_N)$, where α_k is the k -th smallest value of $D_{G_M}^{-1/2} v$.
- $S = \underset{S_k}{\operatorname{argmin}} \varphi_{G_M}(S_k)$, where $S_k = \{\alpha_1, \dots, \alpha_k\}$, $1 \leq k \leq N$.

The sets S and \bar{S} are two disjoint clusters for the heterogeneous network G .

3 – Apply recursive bipartitioning to find multiple HIMs

We then utilize recursive bipartitioning to find multiple HIMs. We use a very different strategy than the one in Benson et al. (2016) to select which cluster to split at each iteration, in order to specifically allow overlapping motif clusters (HIMs) with shared TFs. At each iteration, we split one HIM into 2 child HIMs. After iteration $\ell - 1$, there are ℓ HIMs: S_1, S_2, \dots, S_ℓ .

At next iteration ℓ , one HIM S_k is selected if the graph it forms, G_k , has the lowest subgraph conductance value $\varphi_M^{G_k}$ among $\varphi_M^{G_j}$, $1 \leq j \leq \ell$. We set a threshold t_1 for $\varphi_M^{G_k}$. If $\varphi_M^{G_k} \leq t_1$, S_k will be split into two child HIMs $S_k(c)$ and $\overline{S_k(c)}$ by treating the induced heterogeneous subnetwork as a new network G_k and repeating Steps (1) and (2) for graph G_k . However, if the partition of graph G_k would

lead to zero motif occurrence in either of its child graphs, we would stop partitioning this graph, add a large enough penalty value to its conductance value (to make sure it would not be selected to partition again), and move on to the next iteration. Otherwise, when $\varphi_M^{G^k} > t_1$, the recursive bipartitioning process will stop as all the HIM's subgraph conductance value passes the threshold.

4 – Find overlapping HIMs

Finally, we reconcile the HIMs from the clustering history tree to find overlapping HIMs. This step is added because the HIMs after Step (3) share no TFs. To resolve this, we first trace back the ancestral HIMs up to certain generations for each HIM based on the conductance value of its ancestor $\varphi_M^{G^{anc_i}}$, where $i = \{1, 2, 3 \dots\}$ denotes for the timing of ancestors (e.g., ‘parent’, ‘grandparent’) of the HIM. We trace along the tree until $\varphi_M^{G^{anc_i}} \leq t_2$, where t_2 denotes another threshold. Clearly, t_2 has to be smaller than t_1 to make this process practical. Next, we pool together the TFs from the HIM and from its ancestor HIMs. We sequentially remove the pooled TFs from the HIM. Each time, we remove the TF that contributes the least number of occurrences of the subgraph M in the graph that this HIM represents. We stop the process when removing a TF would significantly decrease the number of occurrences of the subgraph M .

Pseudocode and runtime analysis of our algorithm

The pseudocode of our MOCHI algorithm is presented in Supplemental Methods. The runtime of MOCHI is bounded by $O(t^2 c^2)$, where t and c ($t \ll c$) are the number of TFs and the number of gene loci in the input heterogeneous network, respectively (detailed analysis in Supplemental Methods).

Summary of the algorithm

Given a heterogeneous network from chromatin interactome network and GRN, our algorithm MOCHI identifies multiple and overlapping HIMs, which represent clusters of genes and TFs where the genes are interacting more frequently than expected and are also co-regulated by the same set of TFs. MOCHI has a few key differences as compared to the subgraph conductance method in Benson et al. (2016). First, the input of our algorithm is a heterogeneous network with different types of nodes (TFs and gene loci), which are treated differently, while the input network for the method in Benson et al. (2016) is rather homogeneous. Second, the algorithm in Benson et al. (2016) will not explicitly identify multiple overlapping clusters. In MOCHI, we further developed a recursive bipartitioning method to find multiple HIMs that may overlap. Specifically, we selected a HIM to split if it has the smallest motif conductance among the HIMs at each iteration. In other words, we split the HIM that has the clearest pattern of multiple clusters. HIMs with overlapping TFs will be split in the late stage of iterations, and the overlapping information is encoded in the clustering history tree.

The recent method on hypergraph clustering (Li and Milenkovic 2017) can be applied to identify non-overlapping HIMs where a hyperedge is defined as the motif M . However, similar to the method in Benson et al. (2016), it was not designed to identify overlapping clusters, i.e., the method would not be able to find multiple overlapping HIMs. Our method also has clear differences as compared to previous works on multi-layer network clustering (see review in Kivelä et al. (2014)). First, the inputs are different. A multi-layer network typically has only one type of nodes and different types of interactions connecting nodes within the same layer and between layers. The heterogeneous network in this work has different types of nodes (TFs and gene loci) and also different types of edges. Previous multi-layer network clustering methods are therefore not directly applicable to identify HIMs. Second, the outputs are different. The majority of multi-layer network clustering methods aim to find clusters that are either consistently observed across multiple layers or observed only in a specific layer, which are conceptually different from HIMs.

Software availability

The source code of our MOCHI method can be accessed in the Supplemental Material and at GitHub: <https://github.com/ma-compbio/MOCHI>.

Figure legends

Figure 1: Workflow of our MOCHI algorithm and output examples of HIMs. The network has both gene-gene spatial proximity and TF-gene regulation relationships. **(A)** A 4-node motif M represents the smallest HIM. Here a directed interaction represents a TF-gene regulation relationship, and an undirected interaction represents that the two genes are spatially more proximal to each other than expected. **(B)** Given a heterogeneous network G , we find HIMs by minimizing the motif conductance (see Eq. (2)). **(C)** We compute the subgraph adjacency matrix W_M with $[W_M]_{ij}$ being the number of occurrences of M that have both nodes i and j . **(D)** The weighted network G_M is defined from adjacency matrix W_M . **(E)** Spectral clustering will find clusters in G_M . We recursively apply the method to find multiple HIMs and overlapping HIMs. **(F-G)** Two HIMs as examples in GM12878. **(H)** Example of two overlapping HIMs in GM12878 sharing 7 TFs (the group with pink nodes in the middle). TFs in orange and pink nodes form one HIM with their target genes (bottom left). TFs in pink and blue nodes form another HIM with their target genes (bottom right). Note that the directed interactions from TFs to their target genes are bundled.

Figure 2: HIMs tend to be close to nuclear interior, in particular, speckles. **(A)** Scatter plot shows the mean SON TSA-seq score and mean Lamin B TSA-seq score of the genes in each HIM. Each dot represents a HIM. The curves on the top and on the right are cumulative density functions (CDF). The red vertical dotted line represents the mean SON TSA-seq at 0.284 (approx. within 0.518 μ m of nuclear speckles (Chen et al. 2018)). The black arrow points to HIM #541. **(B)** HIM #541 with low mean SON TSA-seq (pointed by the arrow in **(A)**). The heatmap shows the upper-triangle part of the Hi-C contact matrix (O/E) of the 10kb-sized bins in the chromosome region that covers the genes in this HIM. Target genes of different TFs, gene members of HIM, SON TSA-seq, LaminB TSA-seq, A/B compartments, and RNA-seq signals are shown in different tracks. **(C)** Barplot shows the proportion of HIMs with a varied proportion of genes in A compartment. **(D)** Venn diagram shows that the genes assigned to HIMs are enriched in A compartment. **(E)** Violin and boxplot compare the replication timing of the genes assigned to HIMs and the other genes in the heterogeneous network of K562. Here the HIMs are identified in K562. The spatial localization features of HIMs in other cell types are in Supplemental Figure S9.

Figure 3: HIMs are enriched with essential genes, super-enhancers, and protein-protein interactions. **(A)** Barplots show the proportions of genes that are K562 essential genes among the genes assigned to HIMs and those not assigned to HIMs. **(B-C)** Functional properties of the genes in the identified HIMs in K562. To make a fair comparison, we group the genes assigned to HIMs by chromosome number and called the resulting clusters as merged-HIM clusters. Similarly, we derived non-HIM clusters from the genes in the heterogeneous networks but not assigned to HIMs. P -values are computed by the paired two-sample Wilcoxon rank-sum test. **(B)** Boxplot shows the average gene expression level of the genes in a cluster. **(C)** Boxplot shows the normalized number of super-enhancers related to a cluster. **(D-E)** TFs in HIMs are enriched with protein-protein interactions (PPIs) among themselves.

(D) One example of HIM from GM12878 shows that 9 TFs in the HIM are connected by 14 PPI interactions. The sub-PPI network has a density at 0.389. The TFs NR3C1 and TFEB are master TFs in GM12878. **(E)** Boxplots show the distribution of the sub-PPI network density of the HIMs and the subsets of HIMs with at least n TFs, $n = 5, 10$. The medians are significantly ($p < 2.22 \times 10^{-16}$) higher than the expected density (0.158, red line) of the sub-PPI networks induced by randomly sampled TFs.

Figure 4: HIM comparisons in terms of genes and TFs across the cell types. **(A)** Venn diagram shows the assignment of genes in HIMs across five cell type. Numbers in each facet represent the gene number in each possible intersection relationship across five cell types. **(B)** A NHEK HIM with 3 genes only assigned to HIMs in NHEK. All of its genes are involved in keratinization pathway. Here the top and bottom nodes are the TFs and genes in the HIM, respectively. **(C)** Barplot shows the assignment of essential genes and housekeeping genes to HIMs across five cell types. **(D)** Scatter plot shows the mean SON TSA-seq and Lamin B TSA-seq scores (in K562 (Chen et al. 2018)) of the 30 GM12878 HIMs that are inferred as close to nucleoli in GM12878 (Quinodoz et al. 2018). The red vertical dotted line represents the mean SON TSA-seq score at 0.284. **(E)** The log-transformed ratio of Jaccard index on the genes/TFs between paired HIMs from different cell types over the expected Jaccard index between random control sets. **(F)** Fold changes of motif M density and Hi-C edge density of each HIM between the cell type in which it is identified and another cell type. Here a vertical dash line represents the median of a variable. **(G)** Boxplots represent the distribution of Jaccard index on the TFs of paired HIMs with different numbers of shared housekeeping genes.

Figure 5: A K562 specific HIM with K562 specific chromatin interactome and functional annotations. **(A)** The 45 degree rotated upper triangle part of the contact matrix between the 10kb-sized bins in a chromosome region in K562. The region is segregated into 4 nested TADs. The 3D model on top left is inferred by Chrom3D using 10kb resolution Hi-C data. **(B)** Thin bars represent the transcriptional start sites (TSSs) of the genes that are in the heterogeneous networks. Thick bars represent the genes that are regulated by BCL6B or CPEB1 in K562. **(C)** The assignment of the genes to HIMs in K562 and the other cell types. **(D)** The assignment of the bins to A/B compartments. **(E)** The regions that are annotated as super-enhancers (SE). **(F)** The chromatin states inferred by ChromHMM based on multiple histone modification marks, where red and purple colors represent promoters, orange and yellow stand for enhancers, green represents transcribed regions, gray represents other types of regions such as repressed regions.

Figure 6: Illustration of the spatial organization of HIMs inside the nucleus. The cartoon on the left demonstrates how chromosomes (curved lines) are intertwined in 3D space. Each chromosome can be primarily partitioned into active A compartment (red) and inactive B compartment (blue). Active and inactive genomic regions are formed in 3D space through *cis*- and *trans*-contacts, revealing shared localization relative to subnuclear structures, such as nuclear speckles and nuclear lamina. Similarly, the spatial localization of TFs within the nucleus are not randomly distributed but shows a great level

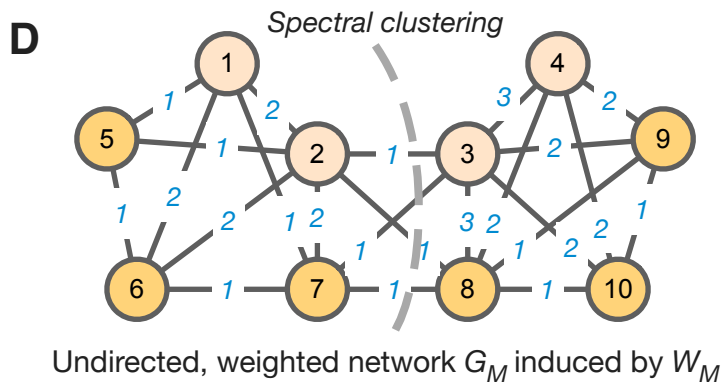

of heterogeneity, probably affected by the distribution of binding sites on the 1D genome and the chromatin openness. As an example, ETV6 is highlighted. The MOCHI algorithm developed in this work is able to identify HIMs (shaded in pink), putative functional modules transiently or stably exist in the nucleus, where a group of TFs exhibit an elevated concentration in a “transcriptional niche” and co-localize with genes in proximity in 3D. For example, a zoom-in view on the right reveals a potential scenario of a HIM where the enhancer and its target genes located far away share binding by a group of TFs and are likely to be pulled together by TFs and co-factors. However, the exact interplay between TFs and 3D genome features and the global formation mechanisms of HIMs have yet to be revealed.
